limb venous glucose concentration was decreased compared to jugular vein glucose concentration and creatinine phosphokinase and D-dimers were increased in both cases. Lactic acid was increased in the hindlimb of Cat 2 compared to the jugular vein.

RESULTS
Both cats had unremarkable cardiac ultrasound and a pulmonary mass was suspected on radiographs and confirmed by computed tomography. CT angiography revealed aortic embolisation in both cases. Cat 1 was treated with enoxaparin and clopidogrel until accessory lung lobe excision, and the post mortem histopathologic diagnosis was adenosquamous cell carcinoma (iliac arteries, accessory lung lobe). Cat 2 had a quadriceps muscle mass originating from the left femoral artery with a cytological diagnosis of reactive fibroplasia (muscle) and the post mortem histopathologic diagnosis confirmed bronchial adenocarcinoma (muscle, left femoral artery, left caudal lung, aortic bifurcation).

STATEMENT
Embolisation in peripheral limb arteries in cats is known to occur as lung-digit syndrome. Neoplastic emboli in the aortic bifurcation or the iliac arteries is a rare presentation with only two published cases confirmed by histopathology, however it should be considered in aged cats without evidence of cardiomyopathy.

Characterisation of canine parvovirus (CPV-2) circulating in the UK
Joanne Brewin1, Elizabeth Graham3,2, Janet Daly1, Stephen Dunham1

3 Cognosco, AnexaFVC, Morrinsville, New Zealand

OBJECTIVES
CPV-2 is a major pathogen of dogs, causing severe haemorrhagic diarrhoea and often death in young puppies. Despite widespread vaccination, the disease continues to occur regularly in small animal practice. Since CPV-2 first emerged in the late 1970s, it has evolved into 3 main antigenic subtypes: 2a, 2b and 2c, completely replacing the original type 2. This study determined which strains of CPV are currently circulating in a sample of dogs living throughout the UK.

METHODS
Thirty-four faecal samples were collected from dogs in the UK, which tested positive for parvovirus by SNAP test or diagnostic polymerase chain reaction (PCR). DNA was extracted from the samples, and approximately 400bp of the capsid protein VP2 was amplified by PCR and sequenced to determine the strain of CPV present.

RESULTS
The predominant strain found was CPV-2b (20/26). A single case of CPV-2c was found and 5/26 were CPV-2a. The last study to characterise CPV in the UK was published in 2008, and also found type 2b as the most common variant. Results from the current study suggest that CPV-2b is still the predominant type, and has not been overtaken by the newer type 2c.

STATEMENT
The current study suggests that CPV-2 in the UK has undergone relatively little change in the last decade. However, CPV continues to evolve and so continued surveillance of strains present in a region is necessary to determine current vaccination efficacy and detect emergence of new antigenic variants; such variants could be more pathogenic or resistant to current vaccines.

Clinical presentation of canine distemper virus infection in dogs in Brazil
Mary Marcondes, Karina Hirata, Jaqueline Azevedo, Wagner Ferreira
São Paulo State University, Araçatuba, São Paulo, Brazil

OBJECTIVES
Canine distemper virus (CDV) infection remains a prevalent disease of the dog in many countries. The aim of this study was to review retrospectively the signalment and clinical presentation of dogs with CDV infection presenting to a veterinary teaching hospital in Brazil.

METHODS
The medical records of 6,700 dogs (January 2014 to December 2015) were evaluated and 74 (1.1%) cases of CDV infection were diagnosed.
